ABSTRACT

Background: Preliminary data suggest that hypocalcemia is common among patients with COVID-19 admitted to the hospital. Objective: The objective of the study was to examine the clinical significance of hypocalcemia in the setting of COVID-19. Methods: Literature search (PubMed) until August 5, 2020. Search terms include hypocalcemia, COVID-19, mortality, and complications. Retrospective studies are reviewed due to a lack of randomized trials. Results: Prevalence of hypocalcemia among hospitalized patients with COVID-19 ranges from 62% to 78%, depending on the definition of hypocalcemia and patients’ characteristics. In most cases, hypocalcemia is mild to moderate biochemically. Hypocalcemia is a risk factor for hospitalization of patients with COVID-19. In already hospitalized patients, hypocalcemia is significantly associated with increase severity of COVID-19 and its complications, including multigorgan failure, acute respiratory distress syndrome, and death. Hypocalcemia is significantly correlated with inflammatory markers of COVID-19. Causes of hypocalcemia in COVID-19 patients are unclear, but vitamin D deficiency may be a contributing factor. Conclusion: Hypocalcemia is common in hospitalized patients with COVID-19 and carries unfavorable outcomes. Further studies are needed to examine the causes of hypocalcemia in COVID-19 and to see whether normalization of circulating calcium levels improves prognosis.

Key words: Calcium, COVID-19, hypocalcemia, mortality, parathyroid hormone, prognosis, vitamin D

INTRODUCTION

COVID-19 is caused by a newly discovered coronavirus called severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Shortly after, many patients with COVID-19 were admitted to the hospital; few retrospective studies reported a high frequency of hypocalcemia [Table 1].[1-6] The frequency of hypocalcemia in patients with COVID-19 admitted to the hospital ranges from 62% to 78%, depending on its definition and patients’ characteristics.[1-5] In one single Chinese cohort of 304 patients admitted to the hospital, only 22 patients (7%) had hypoglycemia.[7] In the latter study, definition of hypocalcemia was not mentioned, and calcium values most likely were an outlier. In most patients, hypocalcemia was mild to moderate.[1-5] In the report of Liu et al.,[9] only 3 of 107 patients had severe hypocalcemia defined as ionized serum calcium of <1.9 mmol/L.

MECHANISMS OF HYPOCALCEMIA IN COVID-19

Causes of hypocalcemia in general are hypoparathyroidism, vitamin D deficiency, hypomagnesemia, and chronic kidney disease.[8] Hypoparathyroidism can be easily demonstrated by the finding of low or inappropriately normal plasma parathyroid hormone (PTH) levels in the face of hypocalcemia. Unfortunately, no studies assessed PTH values in patients with COVID-19 and hypocalcemia. Sun et al.[2] were the only investigators that measured PTH levels in a small subgroup of 26 patients among their cohort of 241 patients admitted with COVID-19. However, these 26 patients were not hypocalcemic.

Normal total serum calcium: 2.15–2.50 mmol/L. To convert to mg/dl, multiply by 4. Normal range of serum ionized calcium was not reported. NR: Not reported, *IQR: Inter-quartile range. PTH: Parathyroid hormone, LDH: Lactate dehydrogenase
Likewise, Vitamin D serum levels were measured in these 26 patients and were found to be low in all patients [Table 1].

It is not known whether hypocalcemia plays a role in infection with the SARS-CoV-2. In fact, calcium ion was shown to be essential in fusion of coronavirus and its entry into host cells. Therefore, it is tempting to speculate that “consumption” of circulating calcium for the sake of virus entry into host cells might contribute to hypocalcemia. Clearly, this hypothesis requires clarification by further investigations. It is also likely that hypocalcemia in hospitalized COVID-19 and its association with more severe COVID-19 may simply a marker of severe illness. Indeed, it was shown that hypocalcemia was common in patients with critical diseases admitted to the intensive care unit and was associated with poor prognosis.

Impact of hypocalcemia on hospitalization
In the series of 531 patients with COVID-19 reported by Di Filippo et al.,[4] 424 (79.8%) patients were admitted to the hospital. The authors found that serum calcium levels were significantly lower in patients requiring hospitalization than patients who were managed as outpatients, 1.13 and 1.16 mmol/L, respectively (P < 0.001).[4] Moreover, by multivariate analysis, hypocalcemia emerged as an independent risk factor for hospitalization, but not for death.[4] Furthermore, in the study of Wu et al.,[13] hypocalcemia was an independent risk factor for long-term hospitalization (defined as hospitalization longer than 14 days); odds ratio 3.3, 95% CI, 1.4–7.9.

Impact of hypocalcemia on severity of COVID-19
Sun et al.,[3] found that COVID-19 patients with hypocalcemia (total serum calcium <2.0 mmol/L) developed the following complications: 32.6% had multiple organ dysfunction, 14.0% had septic shock, and 16.3% had a cardiac injury, whereas none of the patients with normal serum calcium (>2.2 mmol/L) developed any of these complications. Moreover, in the hypocalcemic group of patients, 34.9% had acute respiratory distress syndrome compared with only 1.6% in the normocalcemic group.[3] In their pooled analysis of 2 small Chinese studies, Lippi et al.,[4] found significantly lower serum calcium levels in patients with severe COVID-19 compared with non-severe disease, weighted mean difference being 0.2 mmol/L, 95% CI −0.25 to 0.20. In the latter study, severe COVID-19 was defined as patients requiring mechanical ventilation, vital life support, or intensive care unit admission.[2]

Impact of hypocalcemia on mortality in COVID-19
Sun et al.,[3] reported a 23.3% mortality rate in patients with COVID-19 and hypocalcemia having median total calcium 1.96 mmol/L (inter-quartile range 1.90–2.00) compared to no mortality among patients with normal serum calcium values. In agreement with these results, Liu et al.,[10] found that COVID-19 patients with poor outcomes (defined as death, admission to intensive care unit or need for mechanical ventilation) had lower serum calcium concentrations compared with patients with favorable outcome, 2.01 and 2.10 mmol/L, respectively, P < 0.001.

Relationship of hypocalcemia to inflammatory markers in COVID-19
Multiple studies have shown a significant association between hypocalcemia and inflammatory markers that reflect the severity of COVID-19. Thus, there was a significant negative correlation between hypocalcemia and plasma levels of C-reactive protein,[2,4] lactic dehydrogenase,[4] and D-dimer [Table 1].[2,4] In addition, patients with hypocalcemia had higher circulating interleukin-6 and pro-calcitonin compared with normocalcemic patients.[3]

Potential complications of hypocalcemia in hospitalized patients with COVID-19
To the best of the authors’ knowledge, so far, no cases of hospitalized COVID-19 were reported to have neurological symptoms of hypocalcemia such as tetany or seizures. Meanwhile, it is known that hypocalcemia is associated with prolongation of QT interval, which is proportional to the degree of hypocalcemia and may cause life-threatening torsade de pointes.[12] Interestingly, in one study, 48.5% (50 of 103) patients with COVID-19 with prolonged QT interval had electrolyte abnormalities.[13] Thus, in these patients, hypomagnesemia was recorded in 30.1% of patients and hypokalemia in 27%,[13] Unfortunately, calcium levels were not reported.[13]

CONCLUSION AND CURRENT NEEDS
Hypocalcemia commonly occurs in hospitalized patients with COVID-19 and carries unfavorable prognosis. Etiology of hypocalcemia in patients with COVID-19 is still unclear but is likely multifactorial. Further studies are urgently needed to examine the causes of hypocalcemia in hospitalized patients with COVID-19. Measurement of ionized serum calcium should be done because it is more accurate than albumin-corrected calcium in critically ill patients.[14] In addition, plasma levels of PTH, magnesium, and 25-hydroxy Vitamin D levels should be measured in all patients with hypocalcemia to clarify the etiology of hypocalcemia. Randomized trials are required to see whether correction of hypocalcemia would lead to the improvement of outcomes.
